Introduction

Biogases can play an important role in a transition away from fossil fuels, but often contain impurities such as siloxanes. SiO₂ molecules generated in the combustion of the siloxanes coalesce together into particles which subsequently form even larger aggregates and deposit on internal parts of combustion equipment. We used angle-dependent light scattering as a quicker and less invasive alternative to ex-situ methods such as TEM to investigate aggregate growth in premixed CH₄/hexamethyldisiloxane (L2)/air flames at various siloxane concentrations, flame temperatures and fuel equivalence ratios.

Experimental setup / procedure

Measurement environment
- Burner-stabilized premixed (methane/air) flames.
- L2 added through bubpler system.
- Temperature controlled through exit velocity gas mixture.

Measurement / detection
- 532 nm cw laser beam directed through the flames.
- Detection of scattered light at four angles simultaneously.
- Calibrated using Rayleigh scattering from SF₆.
- Guinier analysis to determine aggregate size.

Results

- Measured \( R_g \) in the range of 10 to 120 nm.
- Sublinear dependence of \( R_g \) on residence time.

Admixture concentration dependence of growth

Sublinear dependence of \( R_g \) on doping concentration.

Temperature dependence of growth

Non-monotonic dependence of \( R_g \) on flame temperature: \( R_g \) increases with flame temperature up to around 2000 K, but decreases thereafter.

Fuel equivalence ratio dependence of growth

A lean flame environment (\( \phi = 0.8 \)) appears to foster aggregate growth compared to rich (\( \phi = 1.3 \)) and stoichiometric flames in which growth is very similar.

Discussion

- When fixing the initial conditions at the residence time corresponding to the first measurement point, a simple model describing particle evolution as a result of collisional growth and sintering predicts the functional dependence of the growth of particle radii well.
- The relatively limited growth at the highest used flame temperatures is likely because the melting point of SiO₂ (about 2000 K) is exceeded, which quite possibly affects the primary particle size and fractal dimension.

Acknowledgments

The presented work is a continuation of experiments by Jennifer D. Herdman, using a modified setup. This research has been financed by a grant from the Energy Delta Gas Research (EDGaR) program.

For small aggregates the angle dependence of the scattered signal \( I \) can be approximated by:

\[
\frac{I(0)}{I(q)} \approx 1 + \frac{1}{3} q^2 R_g^2, \quad q = 2k \sin \left( \frac{\theta}{2} \right)
\]

where \( k \) is the magnitude of the wave vector, \( \theta \) is the scattering angle, and \( R_g \) is the mass-averaged root-mean-square radius (radius of gyration) of an aggregate.
