

# The wind, the traffic and the buildings: the role of the built environment in determining air pollution exposures

**Suzanne Paulson**

**Department of Atmospheric and Oceanic  
Sciences & IoES**

**UCLA**

# Very Small Particles: lots of spatial heterogeneity

Ultrafine particles are mostly from vehicular emissions. They disappear in around a half an hour: rather than magically going away, they collide and stick to fine particles. As a result, they are highly elevated around roadways compared to everywhere else.

# Hotspots in urban areas

# Measurement Design

# Dealing with the mobile data

- Mobile data gives spatially heterogeneous measurements; sometimes you get 30 in one spot, and sometimes one every 20 m.
- Simple averaging of mobile data (after correction for the wandering GPS signal) ends up looking like a trail of confetti after a parade route.

# Using a line-reference system

- Divide the street into a grid with reference points every  $x$  meters.
  - Each reference point gets 1 value per run. If there are 30 data points, they are averaged. If there are no data points, we interpolate one.
  - This avoids under/overweighting individual “runs” on the route.

At high spatial resolution, mostly see the effects of accelerations around traffic stops.

Need ~20  
repeats under  
similar met  
conditions to get  
a reasonable  
average

**What is the effect of the built environment at the block/neighborhood scale on pollutant concentrations at the street?**

# Site 1: Street canyon

Building height  
(Ft.)

Olive & 12th Site (Street view: heading to South)

## Site 2: One isolated tall building with low traffic

Olive & 12th Site (Street view: heading to North)

# Site 3: One isolated tall building with high traffic

Vermont & 7th Site (Street view: heading to West)

## Site 4: Intermediate buildings in one side and low buildings in the other side of the street

Wilshire & Carondelet Site (Street view: heading to East)

# Site 5: All single story buildings

Temple City & Las Tunas Site (Street view: heading to North)

# Built environment quantitative descriptors

# Intersection PNC (Stationary) vs. Over the site average PNC (Mobile)

(a) Morning

(b) Afternoon

Higher traffic  $\rightarrow$  higher UFP, except at the two sites with extreme built-environments, homogeneous & high or low: the street canyon (*Site1*) and the low, flat bldg. canopy (*Site5*).

**(a) Morning**

**(b) Afternoon**

# Best Explanatory Factor in the Morning: The “Areal Aspect Ratio” = Length scale of buildings over length scale of open space

$$Ar_{area} = \frac{H_{bldg}}{L_{diag} \times \left(1 - \sum S_{bldg} / A_{site}\right)} = \frac{H_{bldg}}{L_{diag} \times (A_{open} / A_{site})} = \frac{H_{bldg}}{L_{open}}$$

$H_{bldg}$ : Mean area-weighted building height

$L_{diag}$ : Diagonal length of block

$S_{bldg}$ : Building surface area

$A_{site}$ : Area of the sampling site

$A_{open}$ : Area of the open space in sampling site

Choi et al., 2016

# Best Explanatory Factor in the Afternoon: Turbulence strength (vertical fluctuations of surface winds, $\sigma_w$ )

# Best Explanatory Factor in the Afternoon:

Turbulence strength (vertical fluctuations of surface winds,  $\sigma_w$ )

Appears to be from non-local emissions

# The effects of building heterogeneity on turbulence in the afternoon:

Higher building heterogeneity appears to enhance surface turbulence, under conditions with moderate winds and an unstable atmosphere

# Summary for Planners:

Built environment and traffic management design characteristics that influence near-roadway exposures to vehicular pollution

| Management                                                                                                                                                              | Suggested Direction                                                                                                      | Approx. Size of Effect                                                        | Atmospheric Conditions & Notes                                                                                                 |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------|
| <b>Areal aspect ratio (<math>A_{\text{area}}</math>)</b><br>$A_{\text{area}}$ combines building area-weighted height, building footprint, and the amount of open space. | Lower building volumes and more open space result in lower pollutant concentrations.                                     | Up to approximately a factor of three.                                        | Important under calm conditions (in the mornings at our sites). Not critical when the atmosphere is unstable.                  |
| <b>Building Heterogeneity</b>                                                                                                                                           | Isolated tall buildings result in lower concentrations than homogeneous shorter or higher buildings with similar volume. | Up to approximately a factor of two.                                          | Important under unstable conditions with moderate winds (afternoons at our sites). Not critical when the atmosphere is stable. |
| <b>Traffic flow</b>                                                                                                                                                     | Lower traffic flow is better, controlling for fleet mix.                                                                 | At a given location, concentrations are roughly proportional to traffic flow. |                                                                                                                                |

# Summary for Planners:

Built environment and traffic management design characteristics that influence near-roadway exposures to vehicular pollution

| Management                          | Suggested Direction                                                                                                                                                         | Approx. Size of Effect          | Atmospheric Conditions & Notes                                                                                           |
|-------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------|--------------------------------------------------------------------------------------------------------------------------|
| <b>Traffic Management</b>           | Fewer stops and smaller queues reduce emissions and elevated concentrations around intersections                                                                            | Cannot estimate from our data   | Concentrations depend on emissions, micro-scale turbulence, dispersion, transport from nearby streets, and other factors |
| <b>Sensitive uses near highways</b> | Further is better, but under normal daytime conditions 500 feet is sufficient. If there are consistent nocturnal surface inversions, much longer distances are recommended. | Up to a factor of four or more. | Much more important during surface inversions, which usually occur during night and can persist through mid-morning.     |
| <b>Airports</b>                     | Site residential and other sensitive uses far from airports.                                                                                                                | Up to a factor of four or more  |                                                                                                                          |
